Abstract: Crosslinking of immunoglobulin E antibodies (IgE) bound at the surface of mast cells and subsequent mediator release is considered the most important trigger for allergic reactions. Therefore, the genetic control of IgE levels is studied in the context of allergic diseases, such as asthma, atopic rhinitis, or atopic dermatitis (AD). We performed genome-wide association studies in 161 Labrador Retrievers with regard to total and allergen-specific immunoglobulin E (IgE) levels. We identified a genome-wide significant association on CFA 5 with the antigen-specific IgE responsiveness to *Acarus siro*. We detected a second genome-wide significant association with respect to the antigen-specific IgE responsiveness to *Tyrophagus putrescentiae* at a different locus on chromosome 5. *A. siro* and *T. putrescentiae* both belong to the family Acaridae and represent so-called storage or forage mites. These forage mites are discussed as major allergen sources in canine AD. No obvious candidate gene for the regulation of IgE levels is located under the two association signals. Therefore our studies offer a chance of identifying a novel mechanism controlling the host's IgE response.

Introduction

Immunoglobulin E (IgE) is the class of antibodies that is most frequently recognized for its role in type I hypersensitivity (allergic) reactions. In predisposed, atopic individuals IgE is produced against specific common environmental antigens. Most of the IgE is bound on the surface of mast cells through the high affinity IgE receptor (FcεRI). Cross-linking of mast-cell bound IgEs by allergens leads to the release of histamine and many other mediators, and subsequently to allergic reactions in the skin, respiratory tract, or other organs [1–3].

Total or allergen-specific IgE levels have been analyzed as correlated endophenotypes for different allergic diseases, such as asthma, atopic rhinitis, or atopic dermatitis (AD). IgE levels were analyzed instead of directly using the disease status, as they show a higher heritability than the disease status and are assumed to be less susceptible to confounding environmental factors [4,5]. The heritability of total serum IgE levels in humans was estimated to be up to 80% [6,7]. In humans, several genome-wide association studies (GWAS) were performed to search for QTL with an influence on IgE levels [5,8–10]. So far, about five IgE QTL have

been identified by this approach. These loci comprise several functional candidate genes such as e.g. the gene encoding the FcεRIα subunit of the high affinity receptor for IgE (*FCER1A*) on HSA 1q23 or the *IL13*, *IL4*, *RAD50* region of HSA 5q31 [3]. The causative mutations underlying these QTL are not yet known.

Dogs are valuable models for many human diseases and the special population structure of purebred dogs greatly facilitates the identification of genetic risk factors [11]. AD occurs in humans and dogs [12–14] and there are certain dog breeds, which are genetically predisposed to develop AD [15–18]. IgE levels in dogs are routinely analyzed to aid in the diagnosis of canine AD. In the last years, it has been recognized that total serum IgE levels do not correlate with AD status in dogs [19]. The level of total IgE in dogs is probably much more influenced by the load of endoparasites than by responses to environmental allergens [20]. However, findings of elevated allergen-specific serum IgE levels are used together with clinical criteria to diagnose canine AD. Allergen-specific serum IgE levels are thus indicative but not pathognomonic for AD as healthy dogs may also show elevated allergen-specific IgE levels [19,21].

The major recognized environmental allergens appear to be similar between humans and dogs and include house dust and storage mites, pollens, moulds, and insects [22]. In temperate climates the house dust mites of the genus *Dermatophagoides* and especially *D. farinae* are considered the most important sources of allergen in humans and dogs and several allergens have been identified on a molecular level [23]. In addition to the “true” house dust mites, most dogs are also exposed to storage or forage mites, most notably *Tyrophagus putrescentiae*, *Acarus siro*, and *Lepidoglyphus destructor*. It has been shown that such mites can be present even in un-opened bags of dry dog food. Under suitable environmental conditions up to 90% of commercial dry foods became contaminated with forage mites within a couple of weeks after opening of the bags [24]. As exposure to forage mites seems to be quite universal in human dwellings and the term “domestic mites” has been suggested for the whole group of house dust and forage mites [25].

We are currently building the LUPA cohort of Labrador Retrievers to gain a better understanding of IgE regulation and its relation to AD. We report here the results of a GWAS with respect to immunological traits in this cohort.

Results

We collected sera from 161 Labrador Retrievers and determined 15 immunological phenotypes consisting of *Dermatophagoides farinae* specific IgG1 and IgG4, total IgE, and 12 additional allergen-specific IgE serum levels against *Dermatophagoides farinae*, *Dermatophagoides pteronyssinus*, *Tyrophagus putrescentiae*, *Lepidoglyphus destructor*, *Acarus siro*, *Alternaria alternata*, *Cladosporium herbarum*, *Aspergillus fumigatus*, *Penicillium sp.*, cat epithelium, flea saliva, and *Blattella germanica*.

A. siro is a storage mite considered to be a possible source of antigens that may provoke AD. We determined the *A. siro*-specific serum IgE levels by an enzyme-linked immunosorbent assay (ELISA) and expressed them in ELISA units (EU). The measured IgE levels ranged from 0 to 3060 EU. The lower reliable detection limit for the *A. siro*-specific IgE level is 150 EU. We treated the IgE levels as a binary trait and considered dogs with more than 150 EU as IgE-responsive to *A. siro* and dogs with less than 150 EU as IgE-negative controls.

We determined the genotypes of 174,376 SNP markers in all individuals. Based on genetic distances between individuals projected into two-dimensional space using multidimensional scaling we excluded three dogs that were outliers, so that 135 *A. siro*-specific IgE responders (cases) and 24 controls remained for the final analysis (Figure S1). We also excluded non-informative markers and markers with low call rates and had 113,021 SNP markers for the final analysis.

For the selection of dogs we had minimized the use of first-degree relatives in order to reduce the stratification of our samples. Nonetheless, in purebred dogs there is always a certain amount of cryptic relatedness present. A preliminary analysis without correction for cryptic relatedness gave a genomic inflation factor of 1.09 indicating a relatively low level of stratification. For the GWAS we used a mixed model approach using the marker-derived kinship matrix as a co-variable to correct for both stratification and cryptic relatedness. After this correction the genomic inflation factor was 1.00. We performed an allelic association analysis and detected one region on chromosome 5 (CFA 5) that was significantly associated with the IgE response to *A. siro*. The best-associated SNPs within the interval, BICF2S2297212 (CFA5:g.79,522,993A>G), showed a raw p-value of 2.14×10^{-9} . This is below the Bonferroni-corrected

significance threshold of 4.4×10^{-7} . We also determined the empirical significance threshold by performing 100,000 permutations with randomly assigned phenotypes, which yielded a genome-wide corrected p-value of 0.001 (Figure 1, Table 1). A second marker at the same locus (BICF2P1022237; CFA5:g.80,037,053C>T) was also significantly associated with the *A. siro*-specific IgE response with a raw p-value of 1.07×10^{-7} . Apart from these two SNPs, no other SNP on any chromosome reached genome-wide significance.

The 27 best associated markers of the GWAS were clustered on CFA 5 in an interval ranging from 79.0–86.7 Mb. Only the 28th best-associated marker resided at a different locus on CFA 37. The observed linkage disequilibrium of the association signals on CFA 5 delineates the associated interval to approximately 3.5 Mb ranging from 79.0–82.5 Mb (Figure 2).

The canine genome annotation still remains imperfect. Therefore, we extrapolated the gene content of the associated region from the orthologous human genome interval. The associated region matches to two counterparts on HSA 16, located between 70.1–74.0 Mb and 74.4–74.7 Mb, respectively (Figure 2). This region is very gene-rich and contains 69 annotated genes in the human genome (NCBI build 37.3). There is no obvious functional candidate gene known to be involved in IgE regulation in the associated interval. However, there are some genes related to the immune system, such as e.g. the interleukin 34 gene (*IL34*), in this interval.

Apart from the association to *A. siro*-specific IgE levels we also found a significantly associated SNP with respect to the allergen-specific IgE levels against *Tyrophagus putrescentiae* (Table 2). The marker BICF2G630182288 at position 33,656,088 on CFA 5 has a raw p-value of 6.10×10^{-8} . This marker is 46 Mb away from the highest association to *A. siro*-specific IgE levels. Interestingly however, the region with the *T. putrescentiae*-specific IgE association also showed a moderate association with respect to *A. siro*-specific IgE levels (Table 2 and Figure 2A).

We further analyzed whether there are any correlations between the *A. siro*-specific IgE responsiveness and the other studied traits. The best-associated SNP for this trait was BICF2S2297212 (Table 1). The A-allele at this SNP had a frequency of 7.8% and occurred almost exclusively in *A. siro*-specific IgE non-responsive dogs. When we grouped the dogs according to their genotypes at the associated SNP, we observed a consistent trend for dogs with the A-allele to have lower total and lower allergen-specific IgE levels with respect to all tested allergens compared to the dogs that were homozygous G/G. The genotype at this SNP had no visible correlation with the *Dermatophagoides farinae*-specific IgG1 or IgG4 levels (Figure 3).

Discussion

Atopy is the predisposition to increased IgE production and immediate hypersensitivity in response to exposure to various environmental allergens [26]. Often, intradermal testing (IDT) and/or allergen-specific serological IgE tests are used to support the clinical diagnosis of canine AD. AD is a complex disease influenced by many genetic and environmental factors [16–18,27,28]. AD affected dogs are often sensitized to the common house dust mite *Dermatophagoides farinae* [29]. However, Roque *et al.* [30] reported controversial findings where significantly higher *Dermatophagoides farinae*-IgE levels were found in non-atopic compared to atopic dogs.

It is well known that *Dermatophagoides farinae* allergens provoke positive immunological reactions in humans and dogs [29]. It has also been reported that storage mites such as *Acarus siro*, *Glycophagus*

Figure 1. A genome-wide association study of the IgE-responsiveness to *A. siro* in Labrador Retrievers performed using a mix-model approach efficiently corrected for the population stratification. The red line indicates the Bonferroni-corrected significance level ($p < 3.9 \times 10^{-7}$). The Quantile-quantile (QQ) plot shows the observed versus expected log p-values (on the top-right). The straight line on the QQ plot indicates the distribution of SNP markers under the null hypothesis and the skew at the right edge indicates that these markers are stronger associated with the *A. siro* IgE response than it would be expected by chance.
doi:10.1371/journal.pone.0039176.g001

domesticus, *Tyrophagus putrescentiae*, and *Lepidoglyphus destructor*, which are closely related to house dust mites, are involved in sensitization and allergy induction in humans [31]. To investigate which factors influence allergen-specific IgE levels in Labrador Retrievers we performed GWAS for 12 allergen-specific IgE levels in addition to total IgE and *Dermatophagoides farinae*-specific IgG1, and IgG4 levels as proposed in a human AD study [32]. It has been reported that 18%–50% of atopic dogs manifest sensitization to *A. siro* [29,33]. We found a significant association of the IgE responsiveness to *A. siro* in Labradors on CFA 5. We performed the GWAS using the allergen-specific IgE levels as the binary trait and we also confirmed these results by treating the IgE levels as continuous trait (data not shown).

The locus of the *A. siro* IgE-responsiveness is located between 79.0 Mb and 82.5 Mb. In the investigated canine chromosomal region no obvious candidate gene for the IgE-responsiveness is located. The interval contains the *IL34* gene encoding a member of the interleukin family, but this gene has so far not been implicated in the regulation of IgE levels [34]. Up till now, the genome region around the *IL34* gene has not been associated with IgE levels in human GWAS [4].

At first glance, it may seem surprising that one locus should influence the allergen-specific IgE levels against *A. siro*, but none of the other allergens. This experimental finding is most likely due to the skewed distributions of IgE responders and non-responders with respect to the different antigens investigated. Our detailed analysis of dogs with “*A. siro* IgE non-responsive” and “*A. siro* IgE responsive” genotypes at the associated SNP revealed a consistent

trend for lower IgE but not lower IgG levels across all antigens in the non-responsive genotype class (Figure 3). Thus, the detected locus on CFA 5 may in fact influence the IgE response in general rather than the IgE response to only *A. siro*. Further studies with increased cohort sizes are necessary to conclusively prove this hypothesis.

In conclusion, we mapped two loci for the IgE response to *A. siro* and *T. putrescentiae*, respectively, in Labrador Retrievers. There is no clear functional candidate gene within the associated regions. Thus, this study might eventually lead to the functional annotation of one or several orphan genes and facilitate a better understanding of the immune response to environmental antigens in dogs and humans.

Materials and Methods

Ethics statement

All animal experiments were performed according to the local regulations. The dogs in this study were examined with the consent of their owners. The study was approved by the “Cantonal Committee For Animal Experiments” (Canton of Bern; permits 22/07 and 23/10).

Animal selection

We collected 161 serum and EDTA blood samples from Labrador Retrievers, including 136 dogs with high *A. siro*-specific IgE and 25 dogs with low *A. siro*-specific IgE serum levels (see below). This work was part of a larger effort to build the LUPA

AD cohort, which currently consists of 302 Labrador Retrievers. The dogs were clinically diagnosed according to established criteria for canine AD [35,36] by the clinical dermatology services of the Universities of Bern, London, Uppsala, Utrecht, or Zurich. Control dogs were also investigated by clinical dermatologists. Among dogs with elevated *A. siro*-specific IgE levels 61 were diagnosed as AD-affected and 75 as controls, whereas among dogs with low levels of *A. siro*-specific IgE 16 were AD-affected and 9 were controls. The samples were recruited from 2008–2010.

DNA samples and SNP genotyping

Genomic DNA samples were isolated from EDTA blood with the Nucleon Bacc2 kit (GE Healthcare). The DNA was genotyped at the Centre National de Génomique, Evry, France using illumina canine_HD chips containing 174,376 SNP markers. Genotypes were stored in a BC/SNPmax Database version 3.4 (BC/Platforms).

Measurements of allergen-specific immunoglobulin serum levels

Allergen-specific serum IgE levels against *Dermatophagoides farinae*, *Dermatophagoides pteronyssinus*, *Tyrophagus putrescentiae*, *Lepidoglyphus destructor*, *Acarus siro*, *Alternaria alternata*, *Cladosporium herbarum*,

Aspergillus fumigatus, *Penicillium sp*, cat epithelium, flea saliva, and *Blattella germanica* were measured by a commercially available test (Allercept™ IgE Test Panel, Heska AG, Fribourg, Switzerland) [37]. The Heska laboratory was not aware of the clinical diagnosis. The assay was considered as positive when the optical density measured at 405 nm was >150 EU. The threshold was set by the company by taking a large number of sera that tested very low in the assay which were then heated each at 56°C for 4 hours to inactivate IgE and tested again. Each heated serum in this group was defined as negative for allergen specific IgE. The mean EU value plus 3 standard deviations for the group of negative sera was calculated for each of the different allergens, and then an average mean plus 3 SD for all allergens was calculated (150 EU) and used as the cut off.

Total serum IgE levels were also determined by ELISA. Briefly: Plates (Thermo, VWR) were coated with anti-canine IgE monoclonal antibody D9 [38]. Blocking of non-specific binding sites followed, before addition of the test sera, or of purified canine IgE (Bethyl Laboratories, Inc.) used to generate a standard curve on each plate. The canine sera were serially twofold diluted starting at a dilution of 1:100. After incubation and washing, biotinylated monoclonal anti-canine IgE antibody 5.91 [39] was added for 1 h, followed by extravidine-alkaline phosphatase (Sigma). The plates were then developed with a of phosphatase

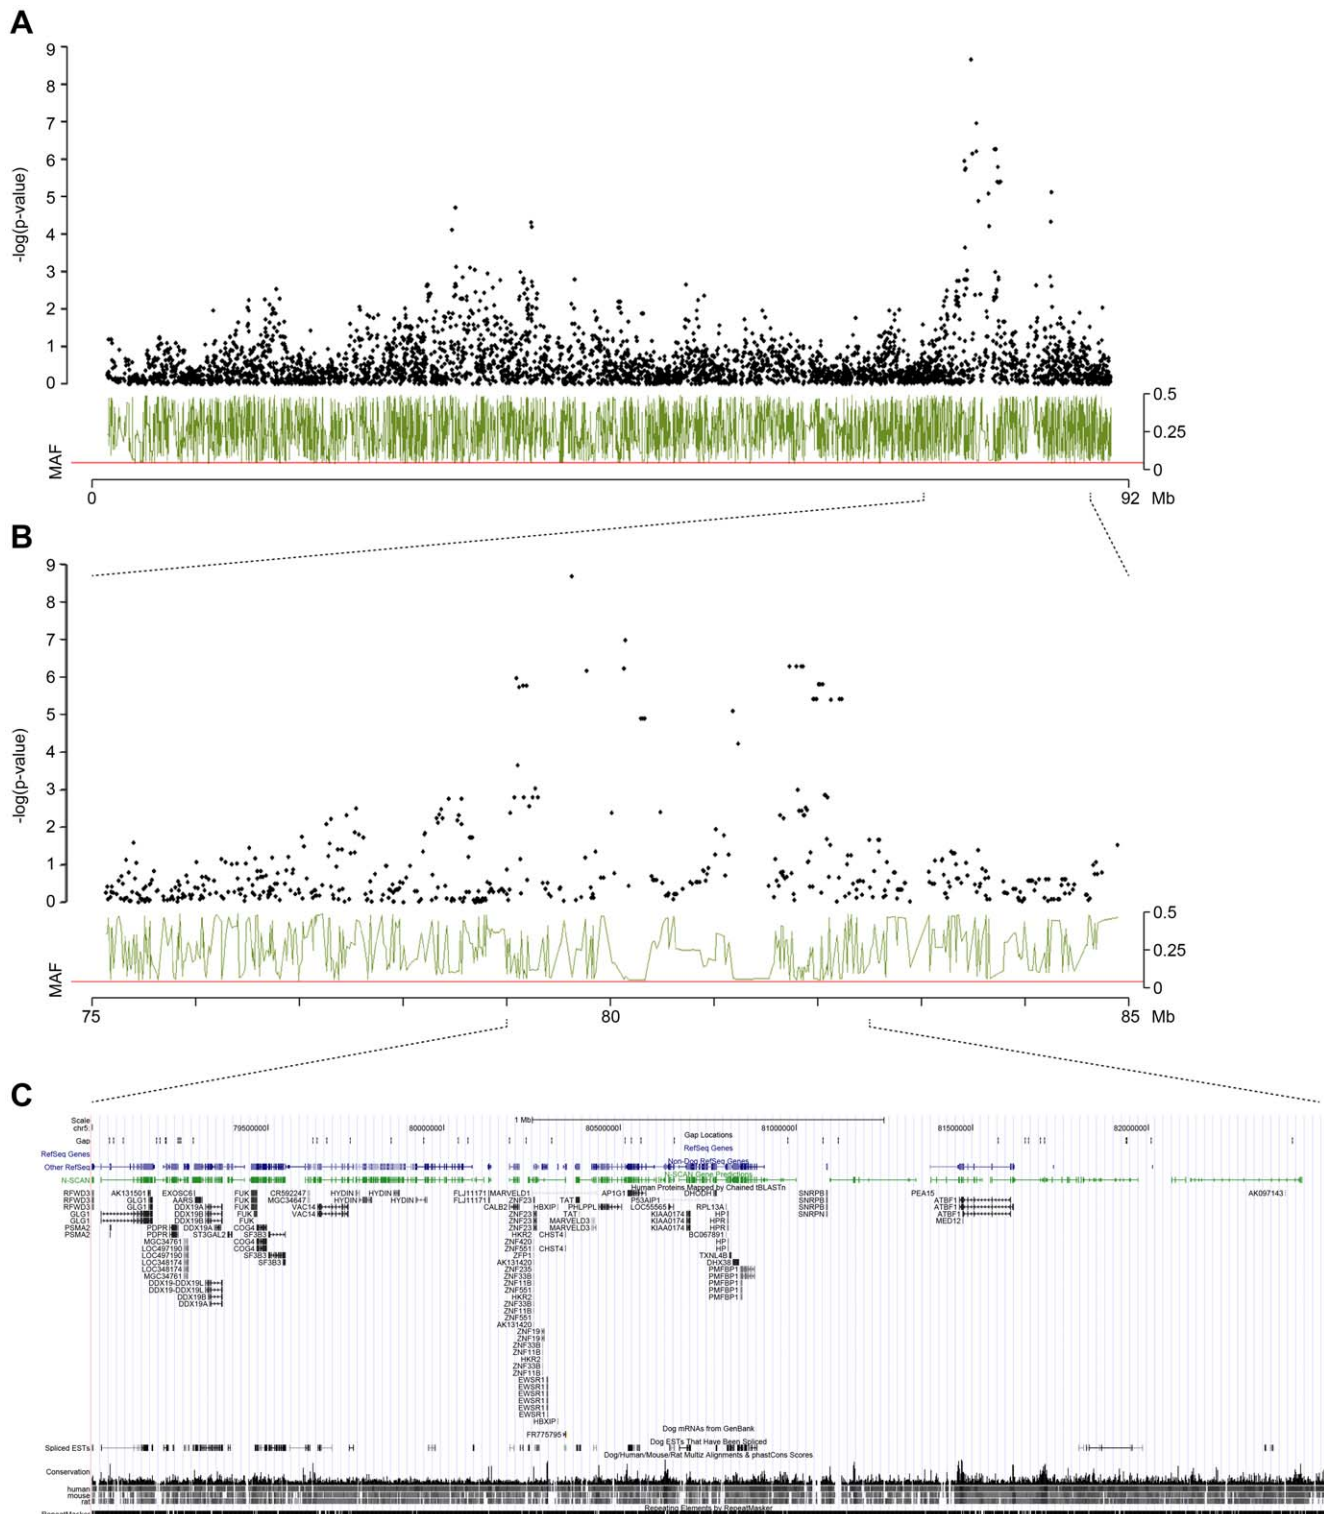

Figure 2. Results of the genome-wide association study restricted to SNP markers located on CFA5. (A) GWAS in the cohort of 161 Labrador dogs showed a significant association of the elevated *A. siro* specific IgE levels in 136 *A. siro* IgE-positive dogs and 25 *A. siro* IgE-negative dogs. **(B)** Associated SNP markers (black) and minor allele frequency (green) at the locus of the IgE-responsiveness to *A. siro* zoomed into the interval between 75 Mb and 85 Mb. **(C)** The gene content of the 3.5-Mb chromosomal interval estimated according to the dog build 2 and displayed using UCSC Genome Browser (<http://genome.ucsc.edu>). doi:10.1371/journal.pone.0039176.g002

substrate (Sigma) in diethanolamine (Fluka) solution. Absorbance readings were measured at 405 nm. The values of the test sample were calculated from the standard curve using an ELISA software

program (SOFTmax[®] 2.31 for Windows[™], Molecular Devices Co., Sunnyvale, CA, USA).

<i>Dermatophagoides farinae</i> IgG1	67	81	12	BICF2P376143	51,541,485	4.02 × 10 ⁻⁵	0
<i>Lepidoglyphus destructor</i> IgE	24	137	12	BICF2P376143	51,541,485	5.81 × 10 ⁻⁵	0
<i>Cladosporium herbarum</i> IgE	12	149	36	BICF2G630756211	31,175,618	7.09 × 10 ⁻⁵	0
<i>Dermatophagoides farinae</i> IgG4	72	76	12	BICF2P376143	51,541,485	7.77 × 10 ⁻⁵	0

Associations exceeding the Bonferroni-corrected significance threshold of $P_{raw} = 4.4 \times 10^{-7}$ are shown in bold.

^aChromosome with the best associated marker.

^bNumber of SNPs at the locus with $P_{raw} < 10^{-6}$. Purebred dogs typically show long-range linkage disequilibrium within breeds. Therefore, strong association signals within dog breeds are often supported by multiple SNPs within a 1–2 Mb interval.

^cThis SNP had a p-value of 7.66×10^{-5} in the GWAS with respect to *A. siro* specific IgE levels. *T. putrescentiae* and *A. siro* both belong to the group of storage mites.

doi:10.1371/journal.pone.0039176.t002

Figure 3. ELISA measurements of 15 immunological phenotypes depending on the genotype at SNP BICF252297212. The G-allele at this SNP was associated with the allergen-specific IgE response to *A. siro*. Note that dogs with the homozygous G/G genotype show a consistent trend for higher IgE levels across all measured antigens. Boxes represent the 25th and 75th percentile of the phenotypic distribution with the median indicated by a solid horizontal line. The whiskers indicate the minimum and maximum of the distributions. Outliers that are more than 1.5 times the interquartile range away from the median are shown as open circles. Abbreviations for allergens: Df, *Dermatophagoides farinae*; Dp, *Dermatophagoides pteronyssinus*; Tp, *Tyrophagus putrescentiae*; Ld, *Lepidoglyphus destructor*; As, *Acarus siro*; Aa, *Alternaria alternata*; Ch, *Cladosporium herbarum*; Af, *Aspergillus fumigatus*; Ps, *Penicillium sp.*; Cat, cat epithelium; Flea, flea saliva; Bg, *Blattella germanica*. doi:10.1371/journal.pone.0039176.g003

Relative concentration of the IgG subclasses IgG1 and IgG4, specific for *Dermatophagoides farinae* were determined in the sera of AD and control dogs. 96 well plates (Thermo, VWR) were coated with *Dermatophagoides farinae* extract (Allergomed AG, 4106 Therwil, Switzerland). After blocking, dog sera were serially twofold diluted and added to the plate. A serum pool from dogs immunized with *Dermatophagoides farinae* was used to generate a standard curve on each plate. After incubation and washing, monoclonal antibodies specific for canine IgG1 (clone B6) or IgG4 (clone A5) were added to the plates [40]. An alkaline phosphatase-conjugated affinity purified goat anti-mouse IgG (Jackson ImmunoResearch Inc.) followed. Plates were then developed with phosphatase substrate. Absorbance readings and calculating of IgG1 or IgG4 levels in relative ELISA units were performed as described above.

The *Dermatophagoides farinae* specific IgG1 and IgG4 as well as the total IgE serum levels were transformed into categorical traits by using the median as cut off.

Genome-wide association studies

We used GenABEL [41] to perform genome-wide association analyses (GWAS). We removed markers with call rates <95% and individuals with call rates <90% from the analysis. For analyses with respect to *Dermatophagoides farinae* specific immunoglobulin levels (IgG1, IgG4, IgE), we removed 13 dogs that had received allergen-specific immunotherapy with *Dermatophagoides farinae* extracts. We also removed markers with minor allele frequency (MAF) <5% and markers strongly deviating from Hardy-Weinberg equilibrium ($p < 10^{-5}$). We performed an allelic association study using the h2a2 function, which uses a mixed-model approach, which uses the kinship matrix estimated from the

marker data to correct for population stratification. Significance levels were determined by the Bonferroni correction ($p_{\text{Bonf}} = 0.05 / \text{number of markers}$). Additionally, empirical significance thresholds were also determined by performing 100,000 permutations of the dataset with arbitrarily assigned phenotypes.

Gene analysis

We used the dog build 2 and the human build 37 assemblies for all analyses. We used BLASTN searches to define the orthologous human chromosomal regions corresponding to the associated interval on CFA 5. For the candidate gene inspection we used the human annotation provided by NCBI (build 37.3).

Supporting Information

Figure S1 Multidimensional scaling (MDS) plot showing the genomic kinships between the analyzed Labrador Retrievers. This plot visualizes the overall genetic distances between the dogs based on 2,000 markers randomly selected out of the total of 113,021 SNP markers. Cases and controls do not form separate clusters, which is an essential prerequisite for a successful GWAS. (TIF)

Acknowledgments

The authors are grateful to referring veterinarians and to all dog owners and breeders who donated blood and serum samples and shared pedigree data. We thank Doug J. DeBoer and Bruce Hammerberg for supplying antibodies and we appreciate the technical assistance of Brigitta Colomb, Christoph Prisi, and Susanne Roth. We thank Heska and especially Dr. Michal Dérér and his team for the very efficient determination of allergen-specific IgE levels.

Author Contributions

Conceived and designed the experiments: PR EM TL. Performed the experiments: MO-L BL VM SM. Analyzed the data: MO-L BL MK KT
